INTRODUCTION

The increased reliance on short- and long-term planning by organizations creates an acute need for population projections. This publication seeks to fill this need. The report contains population projections for Oregon and its counties by five-year age and sex groups for the period 1980 to 2000.

When used as a part of an overall planning process these projections should be viewed as one of many available tools. These projections are based on assumptions developed in 1983 from knowledge of historical trends between 1970 and 1983 tempered by expectations of the near future. Thus, it is possible that many of the events which will effect population change in Oregon during the next two decades have not been anticipated by the analysts who developed these forecasts. Therefore, when using these or any other set of projections or forecasts, the user should exercise caution, evaluating the congruence between projected population change and population change implied by current population estimates.

CPRC will closely monitor these projections by comparing them to the official state population estimates on an annual basis. If and when the estimates and projections diverge to the extent that the projections are no longer useful, new projections will be issued.

Overall, those responsible for the production of these projections characterize them as conservative. By conservative, it is not implied that these projections reflect a slow growth scenario, but that no drastic changes in observed past trends are forecast in terms of either growth levels or spatial distribution of growth. The assumptions, then, are baseline and reflect no radical departures from the observed past. The following section discusses the projection assumptions in detail.

METHODOLOGY AND ASSUMPTIONS

COHORT-COMPONENT TECHNIQUE

A component technique for population projection relies on separating population change into its components and projecting each component independently. Projecting the components - fertility, mortality, and net migration - separately creates a model which simulates the actual process of population change. Refinement of a component technique into a cohort-component model allows the age and sex structure of the base population to interact with the projected fertility, mortality and net migration to produce projected age and sex cohorts as well as population totals.

We use a cohort-component technique for two reasons. One, the character of an area - whether a county has a large number of young adults or a large number of elderly people, for example - plays a role in determining the effects of given levels of fertility, mortality and net migration. A county with many elderly will experience more deaths and a county with many young adults will experience more births under identical mortality and fertility assumptions. Incorporating age and sex cohort detail into our projection model allows the process of population change to be influenced by the existing character of each county.

The second reason for selecting a cohort-component model is that incorporating age and sex detail into the process yields projected age and sex cohorts. To enhance the usefulness of our projections, we have produced projections of 5-year age cohorts for males, females, and the total population.

The process of a cohort-component technique is mathematically quite simple. The baseline data are 1980 census counts by age and sex for each county and the state. These are then survived forward five years using mortality rates (probabilities of survival) to determine the population aged 5 to 75 and over in 1985. Fertility rates (probabilities of giving birth) are then applied to the female population in childbearing ages to determine the number of births occurring during the period. These births are then the population aged 0 to 4 in 1985. Finally, net migration is distributed by age and sex and added to or subtracted from the survived population. This three-step process is iterated for each time period throughout the period of the projection.

THE FERTILITY COMPONENT

CPRC's projections employ a measure termed total fertility rate in the cohort-component model. The total fertility rate can be defined as the number of births a woman could expect to have during her lifetime if her experience were the same as the experience of all women of childbearing ages today. A total fertility rate of 2.1 is considered replacement level. Total fertility rate is the sum of age specific birth rates (the number of births

to women of an age group divided by the number of women in that age group) multiplied by the number of ages in the age group. Oregon's 1980 total fertility rate is 1.8, using 5-year age groups from 15 to 44 as childbearing years. In the projection model we use 1980 county-specific total fertility rates to represent baseline fertility.

While mortality presents demographers with a steady one-dimensional trend, fertility is a much more volatile force with historical fluctuations up and down. Figure 1 shows fertility rates in Oregon from 1940 to 1980 and projected fertility rates to the year 2000. The baby boom years of the 1950's and 1960's show record high fertility rates of 3.2 and 3.6 respectively, dropping radically in the baby bust years to 2.3 in 1970 and 1.8 in 1980. CPRC's fertility assumption states that fertility rates will increase in the next twenty years, peaking at replacement level of 2.1 in the year 2000.

We substantiate our assumption with evidence which has accumulated over the past several years that young women in the U.S. have stable fertility expectations with an average of 2.0 to 2.1 births per woman. This evidence comes from the Census Bureau's annual Current Population Survey (CPS) in which young wives aged 18 to 24 are asked how many children they expect to have in their lifetimes. Since 1970 young women have consistently indicated their desire for approximately two children. Our assumption, then, indicates that over the next twenty years births will increase to match these fertility expectations and yield approximately 2.1 births per woman in the year 2000.

THE MORTALITY COMPONENT

Demographers generally rely on age- and sex-specific life table survival rates to reflect mortality assumptions in a cohort-component projections model. These survival rates represent the probability that an individual of a given age and sex will survive from time X, the beginning of the projection period, to time X + N, the end of the projection interval, where N is the length of the iterative interval. Thus, life table survival rates show that the probability of a 5-year-old boy surviving to become 10 is over 99.8%, while that of a 65-year-old woman becoming 70 is only 91%.

Figure 2 shows survival rates from CPRC's Oregon Life Table. CPRC developed this life table by modifying the National Center for Health Statistics' U.S. Life Table to represent the mortality experience of the Oregon population between 1970 and 1980. These modifications reflect Oregon's generally higher life expectancies. The most significant difference between Oregon and the U.S. occurs between ages 50 and 70 where survival rates in the U.S. decline at a much faster rate than they do in Oregon.

We maintain the Oregon Life Table, static rates of survival, over the projection period; that is, no trending of life expectancy improvements is done for the period of the projections. Trending of survival rates depicts steady, small increases, with most of the change occurring in the older ages. Though survival rates will continue to increase in the future, our assumption

states that the increases in life expectancies for the next twenty years will have no measurable impact on Oregon population. We base this assumption on observing that Oregon at present has higher rates of survival in those ages most effected by life expectancy improvements and surmising that in the next twenty years the U.S. rates will become more like Oregon's while Oregon rates will change very little.

THE MIGRATION COMPONENT

Migration is the most difficult component of population change to forecast due to its volatility. At the same time, it is often the single largest contributor to population change. Thus, the importance of the net migration assumption in a cohort-component model cannot be overstated.

In these projections the volume of the state-level net migration is independently determined, implicitly based on the evaluation of a number of economic forecasts for the State, the Northwest, and the nation. In a sense, these economic forecasts drive the migration assumption. The state-level net migration is then allocated to each county in accordance with each county's projected share of the state migration. These shares are determined by an examination of both long-term (1970-1983) and short-term (1978-1983) trends in the distribution of migrants by county. The short-term trends are used to distribute net migration to counties during the period 1980 to 1985, while the long-term trends are used from 1988 to 2000. The 1986 to 1987 period is a transition period (where needed) to shift from short-term to long-term distribution in order to smooth the number of migrants assigned to each county. Figure 3 shows the historical and projected net migration for Oregon.

In a cohort-component model the analyst must not only project the level of net migration but also the age and sex distribution of those migrants. In these projections we have estimated the age and sex characteristics of migrants by applying life table survival rates to the 1970 census counts to determine how many individuals within each age and sex category we would have expected in 1980 had there been no migration. Thus, the difference between the survived population and the enumerated population is the number attributed to net migration. From these estimates of the characteristics (age and sex distribution) of net migration between 1970 and 1980 (shown in Figure 4) we distribute the level of net migration projected for 1980 to 2000 to age and sex groups.

Migration distributions were developed for counties or county groups. County groups were composed of counties that had similar patterns of age and sex characteristics and similar levels of migration between 1970 and 1980. Since many counties in the state are sparsely populated, estimates of the age and sex distribution of net migration for these counties were thought to be too unstable for use in a long-term forecast. It is for this reason that county groups were used where levels and composition of migrants were found to be similar.

PROJECTIONS OVERVIEW

These projections show Oregon growing 25.5% between 1980 and 2000, about the same percentage increase in 20 years as that which occurred in the 10-year high growth period of the 1970's. Only 9.5% of that growth is predicted to occur between 1980 and 1990 when Oregon will reach 2,884,000; the remaining 16% of the growth is forecast for the 1990's ending in a population of 3,304,300 in the year 2000. Figure 5 graphs Oregon's actual population from 1940 to 1980 and the projected population from 1980 to 2000.

The projections reflect differing levels of growth among Oregon's counties with the pattern much the same as it was in the 1970's. Deschutes County is predicted to grow the fastest of the counties with Morrow and Washington Counties following closely behind. Since patterns of the past have defined the predicted future, it is not surprising that these are the same counties which grew the fastest in the 1970's.

Worthy of particular note are the changes in age structure which are depicted by these projections. The population pyramids in Figure 6 show the age distribution of the population in 1970 and 1980 and the projected distributions for 1990 and 2000. By the year 2000 the population distribution is more like a rectangle than a pyramid, indicating that each five-year age group contains about the same percent of the total population. The force of the baby boom generation, longer life expectancy, and migrants entering the Oregon population combine to create age groups of more or less equal size by the year 2000. The importance of the older ages increases between 1980 and 2000 as the older population becomes a larger and larger proportion of the total.
